The chemical reaction of vanadium flow battery

Overview

A vanadium flow battery works by circulating two liquid electrolytes, the anolyte and catholyte, containing vanadium ions. During the charging process, an ion exchange happens across a membrane.

A vanadium flow battery works by circulating two liquid electrolytes, the anolyte and catholyte, containing vanadium ions. During the charging process, an ion exchange happens across a membrane.

These two chambers are circulated with electrolytes containing active species of vanadium in different valence states, $\text{VO}^{2+} / \text{VO}^{3+}$ in the positive electrolyte and $\text{V}^{2+} / \text{V}^{3+}$ in the negative electrolyte. During discharge process, VO^{3+} is reduced to VO^{2+} at the positive electrode and V^{2+} is.

The vanadium redox flow battery (VRFB) is one promising candidate in large-scale stationary energy storage system, which stores electric energy by changing the oxidation numbers of anolyte and catholyte through redox reaction. This chapter covers the basic principles of vanadium redox flow.

The electrochemistry of VRFBs is based on the redox reactions of vanadium ions in an electrolyte solution. The battery consists of two tanks containing the electrolyte, which is pumped through the cell where the redox reactions occur. During discharge, the following reactions occur: The reverse.

A vanadium flow battery works by circulating two liquid electrolytes, the anolyte and catholyte, containing vanadium ions. During the charging process, an ion exchange happens across a membrane. This process changes the oxidation states of the vanadium ions, leading to efficient electricity.

As it has been explained in the introduction Chap. 1, a RFB is an electrochemical energy storage system whose principle of operation is based on the electrochemical reaction of two redox couples [48]. As its name suggests, this reaction is the well-known redox (reduction-oxidation) reaction, that.
